This manuscript has recently been accepted for publication in the *ERJ Open Research*. It is published here in its accepted form prior to copyediting and typesetting by our production team. After these production processes are complete and the authors have approved the resulting proofs, the article will move to the latest issue of the ERJOR online.

Summary of the "take home" message: The defective translational control in bronchial epithelial cells from asthma patients is reflected by enhanced responses to viral infection, and (temporarily?) worsened by a respiratory viral infection.

Word count: 800

We thank Dr Fatemeh Moheimani and colleagues for their interest in our paper and their considerations, to which we like to respond.

Our paper in ERJ Open Research is a follow-up on our previous publication in ERJ [1]. There we described an intrinsic defect for translational control of response genes (CXCL8 and IL6) in bronchial epithelial cells from asthma patients, due to a failing cytoplasmic translocation of the translational repressor TIAR (1). As the half-life of response transcripts can be very short, the defect is best visualized by prolonging the half-life of transcripts of response genes. In our studies we used IL-17 to prolong the transcript half-life and TNF-α to induce expression of response genes. The study reported in ERJ Open Research shows that upon an in vivo challenge with rhinovirus 16, the bronchial epithelial cells recovered from patients display further enhanced responses to IL-17 and TNF-α, whereas this is not the case for bronchial epithelial cells recovered from healthy individuals.

There have been several reports indicating that bronchial epithelial cells from asthma patients display intrinsically different responses (referred to in [1]), such as exaggerated production of inflammatory mediators and indeed the different response of miR22 as described by Moheimani et al [2]. Whereas our findings for TIAR may underlie the exaggerated inflammatory mediator production and that of the bronchoconstrictor endothelin-1 in asthma, we have not addressed miR22. Interestingly, in their paper, Moheimani and colleagues show that expression of the transcription factor c-Myc was also enhanced after infection with influenza A virus (H1N1). An important difference between their and our study is that Moheimani and colleagues triggered an epithelial response by infection with H1N1, whereas we exposed bronchial epithelial cells to TNF-α and IL-17, about 3 weeks after these cells had been exposed in vivo to rhinovirus 16. In view of that, the enhanced c-Myc expression is in response to a stimulus, i.e. infection with H1N1. As c-
Myc is a typical response gene, it may well be that this enhanced expression is due to the
tIAR-related defective translational control. Interestingly, two recent papers describe that
tIAR does also interact with nuclear long non-coding RNA molecules, which are considered
to regulate transcription of specific sets of genes. One of these papers in fact shows that
tIAR controls c-Myc expression [3]. Although this remains to be shown for bronchial
epithelial cells from asthma patients, it is in line with the tIAR-related effect on
mitochondrial functioning in asthma [4].

We do agree with Moheimani and colleagues that air-liquid interphase (ALI) cultures of
bronchial epithelial cells are more differentiated and thus may better reflect the in vivo
status than submerged cultures. ALI cultures do lead to the expression of genes involved in
the polarized phenotype of bronchial epithelial cells and thus a defective translational
control may lead to additional response genes being expressed in an exaggerated manner.
Although we consider it likely, formally, however, we have not yet shown that this defective
translational control in submerged cultures of bronchial epithelial cells is also manifest in
polarized bronchial epithelial cells from asthma patients.

As mentioned above, we used IL-17 to prolong half-lives of response transcripts in order to
be able to visualize the defect in translational control. There are several mediators, such as
IL-1β and LPS, but also conditions that are known to prolong half-lives of response
transcripts. Partial inhibition of protein synthesis is one of these conditions that results in
the marked accumulation of response transcripts (also known as superinduction),
outcompeting other transcripts for remaining translation and even lead to an enhanced
protein production [5]. During viral replication, eukaryotic protein synthesis is attenuated
and that may be the reason why Moheimani and colleagues saw an increased expression
and translation in bronchial epithelial cells from asthma patients of c-Myc, which normally
has a half-life of around 10 minutes only. Whereas IL-17 exposure or viral replication may facilitate visualization of the defective translational control, these factors will also markedly contribute to exaggerated responses \textit{in vivo}. We have shown that for IL-17 in conjunction with neutrophilic inflammation in asthma [1]. For viral infections it was shown that interferon and interferon-induced genes, most of which are typical response genes, are enhanced in bronchial epithelial cells from children with asthma upon RSV infection \textit{in vitro} [6], and we showed that with an \textit{in vivo} challenge with rhinovirus 16 in adult patients with asthma [7]. This is despite the attenuated interferon response as reported earlier by Wark and colleagues [8], which among others may relate to IL-33 [9].

The defective translational control varies between patients and, obviously, affects only the response genes that have been transcribed and that are dependent on TIAR for translational control, which however are many [10]. This could explain the heterogeneity in asthma pathophysiology just as well as the proposed epigenetic mechanisms by Moheimani \textit{et al.}
